

**Question 2**

part a, 8%

part b, 4%

(a) (i) Sketch a Hertzsprung–Russell diagram with the following features:

- correctly labelled axes, with a *rough* indication of the range of values on each axis
- the *approximate* evolutionary track of a star like the Sun, from where it leaves the main sequence to when it is a cool white dwarf.

(ii) Outline, with the aid of a sketch, how you would use a star's spectral absorption lines to determine its photospheric temperature.

(b) Describe whether, over any portion of the track you have drawn in part a,

(i) the star becomes variable (and name any type of variable star it becomes)

(ii) the star looks, from its external appearance, like a massive, upper main sequence star.

**Question 3**

part a, 4%

part b, 8%

(a) Outline why a supergiant becomes a Type II supernova.

(b) A typical Type II supernova releases about  $10^{46}$  J of energy into the interstellar medium, of which about 1% is in the kinetic energy of the ejected shell of gas, about 0.01% is in the form of electromagnetic radiation, and the rest is in the form of neutrinos. A diffuse cloud of 10 solar masses, consisting almost entirely of hydrogen atoms, lies some way from the supernova, and absorbs a fraction  $5 \times 10^{-6}$  of the electromagnetic radiation, and a fraction  $5 \times 10^{-5}$  of the kinetic energy of the shell. Calculate the rise in the temperature of the diffuse cloud.

$$\begin{aligned}
 E &= 10^{46} \times 10^{-4} \times 5 \times 10^{-6} + 10^{46} \times 10^{-2} \times 5 \times 10^{-5} \\
 &= 5 \times 10^{36} + 5 \times 10^{39} = 5 \times 10^{36} + 5000 \times 10^{36} = 5005 \times 10^{36} \\
 N_H &= \frac{19.9 \times 10^{30}}{1.673 \times 10^{-27}} \approx 1.2 \times 10^{57} \\
 \frac{N_H}{E} &= \frac{5005 \times 10^{36}}{1.2 \times 10^{57}} = 4.17 \times 10^{-19} \text{ J} = \frac{3}{2} kT
 \end{aligned}$$

$$\begin{aligned}
 T &= \frac{2 \times 4.17 \times 10^{-19}}{3} = 2.78 \times 10^{-19} \text{ K} \\
 &= 2.07 \times 10^{-23} \text{ K}
 \end{aligned}$$
